Contract Number: DE-EE0000459

### Subcontractors

- University of New Mexico (UNM), Albuquerque, NM  
  (Prof. Plamen Atanassov)
- Michigan State University (MSU), East Lansing, MI  
  (Prof. Scott Barton)
- Nissan Technical Center, North America (NTCNA),  
  Detroit, MI (Dr. Nilesh Dale)
- Pajariito Powder, LLC (PPC), Albuquerque, NM  
  (Dr. Bar Halevi)

Project Start Date: August 1, 2010  
Project End Date: July 31, 2015

---

### Overall Objectives and Objectives for Fiscal Year (FY) 2014-2015

The objective of this project is to design non-platinum group metal (non-PGM)-based catalysts and supporting gas transport layers, and optimize both the interfacial reaction zone between the electrode and membrane as well as the underlying gas diffusion medium to meet and exceed DOE goals for application in solid polymer electrolyte fuel cells. This project is focused on materials development and is assisted by employing advanced analytical tools, computation, and testing to improve overall design by gaining a critical understanding of the electrocatalysis pathway in these novel structures. The principle target for the reporting FY was to take the project beyond the first phase, where the project’s go/no-go milestone of 100 mA/cm$^2$ at 0.8 V (internal resistance-free, iR-free) at 80°C, in pure H$_2$/O$_2$, and with 1.5 bar total pressure was met. For this reporting period, the principle objectives were to (a) transition the project from hydrogen/oxygen to hydrogen/air with a slated target of 30 mA/cm$^2$ at 0.8 V, 2.5 bar total pressure and (b) reach an end-of-project target of 1 A/cm$^2$ at 0.4 V (same total pressure), both under 100% relative humidity. On a quarterly timeline basis, the target for scale-up was to achieve 50 g batch size by the fourth quarter FY 2014 and 100 g batch size at the end of the program (second quarter FY 2015). Both of these scale-up targets had a quality control milestone of less than 5% variation of activity as measured with hydrogen/air (2.5 bar total pressure) at 0.8 V. In addition, the project aimed to arrive at a unified understanding of the nature of active sites in these catalysts as well as some preliminary understanding of the mechanistic pathway.

### Technical Barriers

This project addresses the following technical barriers from the Fuel Cells section of the Fuel Cell Technologies Office Multi-Year Research, Development and Demonstration Plan:

(A) Durability (increase the durability/stability of catalysts with cycling)

(B) Cost (eliminate precious metal loading of catalysts)

(C) Performance (increase the specific and mass activities of catalysts)

### Technical Targets

The technical targets for this project are listed in Table 1.

### FY 2015 Accomplishments

Since achieving our go/no go decision target (July 2013), our down-selected catalysts were obtained from University of New Mexico and were referred to as UNM-CTS (mechano-chemical approach using water insoluble nicarbazin) catalysts. In order to transition to areal performance in air, several blends of the down-selected catalysts were made by combining them with a previously developed catalyst from UNM referred to as UNM-CBDZ (prepared using a nonmetal chelating approach using carbendazim material). As per our milestones for areal activity in hydrogen/air (Table 1), we have successfully surpassed the low current density target (30 mA/cm$^2$ at 0.8 V). Our current state-of-the-art for high current density performance stands at 1,050 mA/cm$^2$ using the above-mentioned blends. These results correspond to a 200 g batch size well in excess of the end of the program metrics. In addition, emerging catalysts prepared using an iron-encapsulated metal organic framework (MOF) chemistry approach referred to as NEU-Fe-MOF (from Northeastern University).
University) show great promise for an alternative approach. Preliminary measurements indicate that this material has the potential to meet both the low and high current density areal activity targets in air. Our initial report (the last annual report) showed this data using small batch synthesis (a batch size of less than 1 g). Current efforts include developing approaches for scaling up the synthesis using low cost precursors, and these have achieved 30 g batch size levels. While the low current density performance is well in excess of 30 mA/cm$^2$ (100 mA/cm$^2$ at 0.8 V non-IR-corrected), the high current density target is still a challenge with the current state-of-the-art exhibiting 750 mA/cm$^2$ at 0.4 V non-IR-corrected) short of the targeted 1 A/cm$^2$.

Our current efforts towards scale-up performed by PPC are on target based on the timelines for the slated milestones. At the end of the second quarter, in the second phase of this project, we successfully demonstrated less than 5% variability in performance in the low current density target potential (0.8 V) and approximately 5% variability at the higher current density (0.6 V). These variabilities reflect both inter and intra batch measurements. These data are based exclusively on areal activity measurements made using single cell data in air as per this project’s slated operating conditions (2.5 bar total pressure in air, 100% humidification at 80°C).

Durability measurements conducted on the down-selected UNM-Fe-CTS (Fe-organic charge transfer salt based on nicarbazin) catalysts shows excellent tolerance to catalysts stability tests (based on Nissan protocol, similar to DOE protocol). Carbon corrosion testing that involved load cycling to 1.5 V vs. the reference hydrogen electrode, however, indicated significant losses; these results were similar to losses seen with a PGM cathode.

The understanding of the nature of the active site was significantly advanced in this reporting period with the identification of a dual site mechanism wherein the N$_{2+2}$ site was responsible for the initial adsorption and reduction of oxygen to peroxide moieties followed by a second cascade step of further reduction of the peroxide in surrounding Fe-N$_{x}$ sites. This description of the mechanism was supported with in situ X-ray absorption spectroscopy (XAS) and targeted electrochemical probe measurements.

### INTRODUCTION

Recent reports [1–3] have clearly demonstrated the significant advancements made in enabling good oxygen reduction activity with iron-based non-PGM catalysts. These so called Fe-N$_x$-based systems have evolved over several decades of intense work leading up to the current state-of-the-art, reported recently [1,4]. This report provides for the first time a comprehensive view of (a) the gains in oxygen reduction reaction (ORR) activity derived from materials prepared using current state-of-the-art materials developed by two different university groups (NEU and UNM) and the successful scale-up of these by a startup company, PPC; (b) the successful transition from previous operations in oxygen to air (MSU, NEU, and PPC); (c) excellent durability in terms of catalyst stability (vide DOE and Nissan protocols) (UNM and NTCNA); and (d) a detailed understanding of the nature of active sites and electrocatalytic pathways as distinct from the parallel pathway in alkaline electrolytes (UNM and NEU).

### APPROACH

The approach adopted in this reporting period involved blends of materials derived using two separate approaches: a UNM group’s silica templating methodology referred to as UNM-CTS and a UNM-CBDZ approach. The former (UNM-CTS) was derived using the mechano-chemical approach of ball milling an organic charge transfer salt (nicarbazin) in the presence of Fe salt and the latter using an aqueous formulation of a non-chelating material, carbendazim, with Fe salt, and both were supported on...
A brief summary illustrating these developments is presented showing a nearly 80% improvement in performance in air (compared to previous reporting period) with 70 mA/cm² at 0.8 V and 1,000 mA/cm² at 0.8 V achieved using 3 mg/cm² loading gas diffusion electrodes. Figure 1a shows two separate blend formulations, Gen 1 and Gen 2, made using variations in silica templates. Comparison of Gen 2 (100% CTS batch) and Gen 2A (CTS/CBDZ blend with variation of silica template show remarkable inter batch reproducibility in hydrogen/air performance in accordance to this project’s targeted operating conditions. The low current density target of 30 mA/cm² at 0.8 V (uncorrected) has been met and exceeded with current state-of-the-art performance at 70 mA/cm² current density. The higher current density target of 1 A/cm² at 0.4 V (infrared [IR]-corrected) (second quarter, FY 2015) has nearly been met with current activity at 0.92 A/cm² (uncorrected) and 1.05 A/cm² (IR-corrected). These performance figures are better delineated in the corresponding Tafel (semi-log plot) shown in Figure 1a. Both of these results are reported without any IR correction.

A brief introduction to the NEU catalyst synthesis methodology is reported in Figure 2a, wherein an iron-based non-PGM ORR electrocatalyst utilizes an MOF-based support that hosts a chelated iron complex within its pores. The MOF support was chosen in order to take advantage of the porosity and high surface area, key variables known to improve the catalytic activity and mass transport. A one pot encapsulation procedure developed by NEU uses a zinc MOF (ZIF-8 MOF) synthesized in the presence of chelated iron (or Co) precursors. The final product was dried in a vacuum oven for four hours at 70°C and then further treated by either one or two heat treatments in argon at 1,050°C and ammonia at 950°C, respectively. Preliminary rotating disc electrode (RDE) analysis shown in Figure 2b shows performance exceeding that of platinum in alkaline electrolyte (0.1 M KOH) and a half wave potential difference of 70 mV compared to platinum in acidic pH (0.1 M HClO₄). Non-iron-containing MOF shows, in comparison, 400 mV over-voltage indicating predominant peroxide generation. Preliminary fuel cell measurements made using hydrogen/oxygen (1.5 bar total pressure), 80°C, and 100% humidification indicated performance in excess of DOE Phase 1 target of 100 mA/cm² at 0.8 V (IR-corrected) with current state-of-the-art at 170 mA/cm². More importantly, the hydrogen/air performance meets both the low 0.8 V (IR-uncorrected) and high current density 0.4 V (IR-uncorrected) values with current state of the art at 75 mA/cm² (at 0.8 V) and 1 A/cm² (at 0.4 V).

After a lengthy analysis, PPC identified unique processing equipment and supplies needed for the technology transfer and scale-up. Once in place, lengthy visits by PPC personnel to NEU led to creation of standard operating procedures, and critical points of manufacturing were.
determined to be (1) making the MOF, (2) mixing the MOF and precursors, and (3) pyrolysis both in inert and reactive atmospheres. To establish calibration points of processing equipment a series of materials at the different stages of manufacturing identified have been sent to project partners (NEU and NTCNA) and are being characterized to determine points of congruency in the processing. This procedure allowed baseline levels and sensitivity of processing variables for the key processing steps to be established and used during scale-up.

Scale-up required modification of the both the recipe and procedure used in the key MOF-forming step. First, switching from a small shaker-type mill to a larger planetary ball mill lead to a tendency for powder clumping that is inherent with powder milling. When simply applying NEU’s procedure with a planetary ball mill, the resulting MOF powder included clumps, and the resultant material had a lower surface area than what is required for producing good catalysts. Clumping increased with 10, 20, and 50x batch sizes. Numerous iterations of precursor pretreatments, sequence of addition, and even material ratios were attempted unsuccessfully. Methods were found in the literature and with NEU’s assistance, a formulation that decreased clump formation was successfully achieved even when applied at 50x scale, producing good quality MOF as determined by X-ray diffraction (XRD), Brunauer-Emmett-
FIGURE 2. (a) Schematic showing the one pot synthetic approach for NEU MOF-based iron encapsulated catalysts. Scanning electron microscope micrograph shows encapsulation and carbon fiber formation. (b) RDE comparison with Pt/C (Tanaka 30% Pt/C) in both acid and alkaline pH (0.1 M KOH and HClO4). Also plotted is a non-iron-containing catalyst referred to as Basolite. (c) Tafel plot for single cell data (5 cm²) in H2/O2 with 1.5 bar total pressure, 100% RH, 80°C. Also shown is the corresponding linear polarization data (IR-uncorrected) in H2/air showing the concomitant low and high current density performances under 2.5 bar total pressure.
Teller surface areas at different processing steps, and final catalyst performance. Figure 3a shows the XRD patterns of commercial ZIF-8 MOF, as well as the time trajectory of MOF phase evolution at various milling times, and the final 50x batches used for making the excellent performance MOF-based catalyst shown in Figure 3b. Figure 3b shows the performance of scaled-MOF based catalysts, and improvement in both performance and scale to a final catalyst made at 50x scale (30+ g per batch) with performance after being on-line for more than two hours of more than 100 mA/cm² at 0.8 V, and 800 mA at 0.4 V in 2.5 bar air.

Iron speciation in the Fe-CTS and Fe8AA catalysts was characterized with Fe Mössbauer spectroscopy [5,6] together with in situ XAS (Figure 4). Two iron species (D1 and D2) were identified in the Fe8AA catalyst that resulted in the appearance of two doublets (Figure 1a). D1 and D2 can be assigned to a four-fold nitrogen or nitrogen–carbon coordination of FeII in low-spin (LS) and medium-spin state (MS), respectively [5,7]. Consistently, the Fourier transform of the sole extended X-ray absorption fine structure (EXAFS) peak around 1.5 Å (without phase-correction) is assigned to the Fe-N4 moieties based on EXAFS fitting results. D1 and D2 are the subject of ongoing research related to the exact site structure and to the integration of FeN4 or FeN2C2 moieties that can be viewed either as defect sites within a graphene layer (edge defects) or as a structure bridging two graphene zigzag- or armchair-edges [5,6]. The observed ORR activity has been widely linked to either or both of the D1 and D2 species. In addition to the two doublets (D1 and D2), three more iron species were identified in the Fe-CTS catalyst resulting in a singlet, and two sextets (Figure 1c). The singlet is assigned to either γ-Fe or super paramagnetic iron nanoparticles [5] while the sextet’s parameters match those of α-Fe and iron carbide [5,7]. The coexistence of the Fe-N species and metallic iron nanoparticles (NPs) under reactive conditions in acid are in good agreement with in situ XAS results, the two FT-EXAFS peaks around 1.5 and 2.1 Å are ascribed to the Fe-N scattering and Fe-Fe scattering within pure iron NPs and/or iron carbides, respectively. The long-term existence of metallic iron species in an acidic environment strongly suggests that they are fully wrapped in graphitic layers. These metallic iron species were previously believed to be inactive due to their lack of exposure to the electrochemical environment. However, recently published research by various groups has shown that the nitrogen-doped carbon encapsulating these metallic iron species are highly ORR active [1,8,9]. Therefore, the control over the content in the final products after high-temperature treatment as shown here has enormous consequences on elucidating the fundamental synthesis/morphology/activity correlations for non-PGM catalysts.

**CONCLUSIONS**

- Catalyst blends (1:1) prepared by PPC using 50+ g batch sizes with University of New Mexico catalysts, UNM-CTS and UNM-CBDZ, show inter- and intra-batch variations below 5%. They also meet and exceed the low current density areal activity target in hydrogen/air (2.5 bar total pressure, 80°C, 100% RH). High current density is currently at 920 mA/cm² at 0.4 V. A separate MOF-based approach from NEU shows excellent areal activity under these performance metrics exceeding the low current density benchmark and meeting the high current density target. This approach has been scaled up to 30 g batches.

- Detailed durability studies reported earlier on the UNM catalysts measured by NTCNA indicate excellent tolerance to catalyst stability tests, and relatively poor resistance to carbon corrosion test protocols; the
• NTCNA will perform testing to validate durability under DOE protocols.

• We will further test the validity of the proposed mechanism using the final set of in situ and operando synchrotron XAS data in conjunction with density functional theory calculations. In addition, we will use the in situ spectroscopy to probe degradation pathways.

FIGURE 4 (a-d). M ossbauer spectra collected [5,7] for UNM catalysts, FeAA8Pyr (Fe-Amino-antipyrene) and Fe-CTS (Fe-organic charge transfer salt based on nicarbazin) in consonance with in situ synchrotron XAS in terms of Fe K edge Fourier transform of the EXAFS showing remarkable congruence on identification of the relative presence of Fe-N and Fe-NPS moieties.

FUTURE DIRECTIONS

• The principle focus of the group will be to meet the high current density areal activity target at 0.4 V (IR-uncorrected) using both UNM and NEU blend formulations.

• We will optimize scale-up and MEA fabrication for MOF based catalysts from NEU.
